Columns: "Index", "Timestamp", "Position (m)", "Velocity m/s", "Gravity (m/s/s)", "ARF
 $\text{kg} \cdot (\text{m/s}^2)$ ", "d(t)"

- 1.) According to the table the maximum height that the object reaches is 636.808 meters at 9.05 seconds. (I used an interval of 0.01 seconds but technically I could have gone as accurate as I wanted by changing the "interval" variable in the code.

2.) According to the table the object hits the ground at 21.04 seconds at a velocity of -101.369 m/s.

```
modeling.py
1 import math
2 import pandas as pd
3 import matplotlib.pyplot as plt
4
5 pd.set_option('display.max_rows', None)
6 pd.set_option('display.max_columns', None)
7 pd.set_option('display.width', None)
8
9 thing = pd.DataFrame(columns = ['t','st','vt','at','ARF','dt'])
10 thing.loc[0,'t'] = 0
11 thing.loc[0,'st'] = 200
12 thing.loc[0,'vt'] = 100
13 thing.loc[0,'at'] = -9.81
14 thing.loc[0,'ARF'] = 0
15 thing.loc[0,'dt'] = 0
16 interval = 0.01
17 for i in range(2500):
18     thing.loc[i,'t'] = i * interval
19     thing.loc[i,'at'] = -9.81
20     thing.loc[i,'ARF'] = 6.3 * thing.loc[i,'vt']
21     thing.loc[i,'dt'] = thing.loc[i,'ARF'] / 250
22     thing.loc[i+1,'vt'] = -thing.loc[i,'dt']*interval + thing.loc[i,'at']*interval + thing.loc
23     thing.loc[i+1,'st'] = thing.loc[i,'st'] + thing.loc[i,'vt'] * interval
24
25 thing = thing[['t','st','vt','at','ARF','dt']]
26 print(max(thing['st']))
27 print(thing)
28 plt.figure(1)
```

-Code for project

Figure 1

-Graph of Position vs Time over 25 seconds (sampling every 0.01 seconds)

3.)

a.) The procedure I used to calculate the data for each row is as follows:

- Calculate ARF for current row: multiply 6.3 (constant of air resistance) to the velocity of the current row.
- Calculate $d(t)$ for the current row: divide ARF (current row) by the weight of the object (250 kg).
- Calculate the velocity of the NEXT row: $d(t) * \text{time interval} + a(t) * \text{time interval} + \text{previous velocity}$.
- Calculate position of the next row: $\text{current position} + \text{current velocity} * \text{time interval}$.

b.) The advantage of solving this problem numerically is that it is easier to do and requires less thinking than solving it algebraically.

c.) The disadvantage of solving this problem numerically is that no matter how small you set your time interval you will never get a perfect answer. However if you were able to solve this problem algebraically you would be able to arrive at an exact answer.

d.) Making a table with a smaller time interval (longer table) would increase accuracy and mostly solve the disadvantage of solving this numerically. However a longer table requires more computing power. There are no disadvantages that could not be solved by making a longer table.

e.) The way you would go about creating a table accounting for the decrease in air resistance and force of gravity is by changing each of their equations. EX:

The equation for force of gravity is:

$$a(t) = -9.81$$

It is a constant since we are assuming that it is not changing as height increases. In order to model the change you would have to use an equation that calculation that predicts the force of gravity with respect to position.

The equation would look more like this:

$$a(p) = -9.81/p$$

As position increases the force of gravity decreases. You would incorporate this into the table by adding one extra step: Creating a new column with the instantaneous acceleration due to gravity & instantaneous acceleration due to air resistance.

Note: This program can be used as a calculator for problems like this. As long as you change your starting velocity, position, weight, and time interval you can generate a graph of the position vs time of the object. Further, the more you decrease the time interval the more accurate your guess, therefore the maximum accuracy of your answer is proportional to the computing power you have at your disposal.

Full code for this project is on github:
